Abstract

This paper describes the implementation and evaluation of an operating system module, the Congestion Manager (CM), that provides integrated network flow management and exports a convenient programming interface that allows applications to be notified of, and adapt to, changing network conditions. We describe the API by which applications interface with the CM, and the architectural considerations that factored into the design. To evaluate the architecture and API, we first describe our implementation of TCP, a streaming layered audio/video application, and an interactive audio application using the CM, and show that they achieve adaptive behavior without incurring much end-system overhead. All flows including TCP benefit from the sharing of congestion information, and applications are able to incorporate new functionality such as congestion control and adaptive behavior.

1 Introduction

The impressive scalability of the Internet infrastructure is in large part due to a design philosophy that advocates a simple architecture for the core of the network, with most of the intelligence and state management implemented in the end systems [9]. The service model provided by the network substrate is therefore primarily a "best-effort" one, which implies that packets may be lost, reordered or duplicated, and end-to-end delays may be variable. Congestion and accompanying packet loss are common in heterogeneous networks like the Internet because of overload, when demand for router resources, such as bandwidth and buffer space, exceeds what is available. Thus, end systems in the Internet must incorporate mechanisms for detecting and reacting to network congestion, probing for spare capacity when the network is uncongested, as well as managing their available bandwidth effectively.

Previous work has demonstrated that the end result of of uncontrolled congestion leads to a phenomenon

commonly called "congestion collapse" [7, 12]. Congestion collapse is largely alleviated today because the popular end-to-end Transmission Control Protocol (TCP) [30, 40], incorporates sound congestion avoidance and control algorithms. However, while TCP does implement congestion control [17], many applications including the Web [5, 11] use several logically different streams in parallel, using multiple concurrent TCP connections between the same pair of hosts. As several researchers have shown [2, 3, 27, 28, 42], these concurrent connections compete with – rather than learn from – each other about network conditions to the same receiver, and end up being unfair to other applications that use fewer connections. The ability to share congestion information between concurrent flows is therefore a useful feature, one that promotes cooperation among different flows rather than adverse competition.

Another important trend in today's Internet is the increasing number of applications that do not use TCP as their underlying transport, because of the constraining reliability and ordering semantics imposed by its in-order byte-stream abstraction. Streaming audio and video [24, 34, 41] and customized image transport protocols for JPEG-like formats, where portions of an image can be rendered out-of-order, are important examples. Such applications use custom protocols that run over the User Datagram Protocol (UDP) [29], often without implementing any form of congestion control. The unchecked proliferation of such applications will have a significant adverse effect on the stability of the network [3, 7, 12].

A majority of Internet applications deliver HTML documents and images or stream audio and video to end users and are *interactive* in nature. A simple but useful figure-of-merit for interactive content delivery is the end-to-end download latency; users typically wait no more than a few seconds before aborting a transfer. Therefore, it would be beneficial for content providers to adapt *what* they disseminate to the state of the network, so as not to exceed a threshold latency. Fortunately, such content adaptation is possible for most applications. Streaming audio and video applications typically encode information in a range of formats corresponding to different encoding (transmission) rates

and degrees of loss resiliency. Image encoding formats accommodate a range of qualities to suit a variety of client requirements.

Today, the implementor of an Internet content dissemination application has a challenging task: For her application to be safe for widespread Internet deployment, it must either use TCP, suffering the consequences of its fully-reliable, byte-stream abstraction, or use an application-specific protocol over UDP, but attempt to implement congestion control in it, reinventing this machinery and risking getting it wrong. Furthermore, neither alternative allows for sharing congestion information across flows. In addition, one of the undesirable side effects of the layered protocol stack, the common application programming interface (API) classes—Berkeley sockets, streams, and Winsock [31]— do not expose any information about the state of the network in a standard way to applications[1]. This makes it difficult for applications running on existing end host operating systems to make an informed decision, taking network variables into account, during content adaptation.

This paper describes the implementation and evaluation of an end-host operating system module and its API that enables network-adaptive applications. Here, we build on our recent proposal for a Congestion Manager (CM) [3], an end-system architecture for sharing congestion information between multiple concurrent flows. The advantage of the CM is that it moves the task of performing sound congestion control to a trusted kernel module, freeing transport protocols and applications from having to re-implement it and ensures that the *ensemble* of concurrent flows is not overly aggressive to the network.

While our previous work provided the rationale for such an approach and laid out an initial design for the CM, this paper details the design and implementation of the CM architecture and describes how it collects end-to-end information about the network and provides it to applications through its API. We show using specific case studies how applications can adapt their transmissions to changing network conditions using the CM API. Conceptually, our system is based on feedback in the form of *callbacks* from the in-kernel CM to an application that are used to orchestrate its transmissions. We show that our implementation of callbacks does not affect performance or scalability of a data sender.

To our knowledge, this is the first implementation of a general application-independent system that combines *integrated flow management* with a convenient API for content adaptation. The end-result is that applications achieve the desirable congestion control properties of long-running TCP connections, together with the flexibility to adapt data transmissions to prevailing network conditions.

Another important contribution of this paper is to demonstrate that the CM extensions are useful even when applied to the sender side alone, requiring no changes to the data receiver. Because most robust congestion control algorithms rely on receiver feedback, it is natural to expect that a CM receiver is needed to inform the CM sender of successful transmissions and packet losses. However, to facilitate deployment, we have designed our system to take advantage of the fact that several protocols including TCP and other applications already incorporate some form of application-specific feedback.

We demonstrate the benefits of integrated flow management and show how applications can adapt their transmissions using callbacks initiated by the kernel. We do this by answering the following key questions in this paper: Does the CM provide a convenient interface for applications such as streaming layered video/audio, real-time audio, and TCP to adapt without placing a significant burden on developers? What information is needed from applications for the correct functioning of the system? In today's off-the-shelf operating systems, does the CM place any performance limitations upon applications?

We answer these questions based on our implementation of the CM in the Linux operating system and its measured performance over a variety of TCP and UDP applications. We find that our implementation of TCP (which uses the CM for its congestion control) has essentially the same performance as standard TCP, with the added benefits of integrated congestion management across flows. Our implementation of a layered streaming audio/video application demonstrates that CM architecture can be used to implement highly adaptive congestion controlled applications. Adaptation via the CM API helps these applications achieve better performance and also be fair to other flows on the Internet. We find that the API introduces a negligible to observable (between 2.5% and 18.5%) CPU overhead depending on the type of callback used, but that the higher CPU utilizations occur when the application desires very fine-grained about the network on a per-packet basis. We do not believe this is a bad trade-off, especially because our mid-range PC sender (350 MHz Pentium) easily saturates a 100 Mbps Ethernet despite this overhead. We have also CM-enabled a legacy application—the Internet audio tool *vat* from the MASH toolkit [22]—to perform adaptive real-time delivery. Since less than one hundred lines of source code modification was required to CM-enable this complex application and make it adapt to network conditions, we believe it demonstrates the ease with which the CM makes applications adaptive.

The rest of this paper is organized as follows. Section 2 describes our system architecture and implementation. Section 3 describes how network-adaptive applications can be engineered using the CM, while Section 4 presents results of several experiments. In Section 5,

---

[1] Utilities like `netstat` and `ifconfig` provide some information about devices, but not end-to-end performance information that can be used for adapting content.

we discuss some miscellaneous details and open issues in the CM architecture. We survey related work in Section 6 and conclude with a summary in Section 7.

2 System Architecture and Implementation

The CM performs two important functions. First, it enables efficient multiplexing and congestion control by integrating congestion management across multiple flows. Second, it enables efficient application adaptation to congestion by exposing its knowledge of network conditions to applications. Most of the CM functionality in our Linux implementation is in-kernel; this choice makes it convenient to integrate congestion management across both TCP flows and other user-level protocols, since TCP is implemented in the kernel.

To perform efficient aggregation of congestion information across concurrent flows, the CM has to identify which flows potentially share a common bottleneck link *en route* to various receivers. In general, this is a difficult problem, since it requires an understanding of the paths taken by different flows. However, in today's Internet, all flows destined to the same end host take the same path in the common case, and we use this group of flows as the default granularity of flow aggregation[2]. We call this group a *macroflow*: a group of flows that share the same congestion state, control algorithms, and state information in the CM. Each flow has a sending application that is responsible for its transmissions; we call this a *CM client*. CM clients are in-kernel protocols like TCP or user-space applications.

The CM incorporates a *congestion controller* that performs congestion avoidance and control on a per-macroflow basis. It uses a a window-based algorithm that mimics TCP's additive-increase/multiplicative decrease (AIMD) scheme to ensure fairness to other TCP flows on the Internet. However, the modularity provided by the CM encourages experimentation with other non-AIMD schemes that may be better suited to specific data types such as audio or video.

While the congestion controller determines what the current window (rate) ought to be for each macroflow, a *scheduler* decides how this is apportioned among the constituent flows. Currently, our implementation uses a standard weighted round-robin scheduler whose weights are settable by an administrator.

In-kernel CM clients such as a TCP sender use CM function calls to transmit data and learn about network conditions and events. In contrast, user-space clients interact with the CM using a portable, platform-independent API described in Section 2.1. A platform-dependent CM library, `libcm`, is responsible for interfacing between the kernel and these clients, and is de-

---

[2] This is not strictly true in the presence of network-layer differentiated services. We address this issue later in this section and in Section 5.

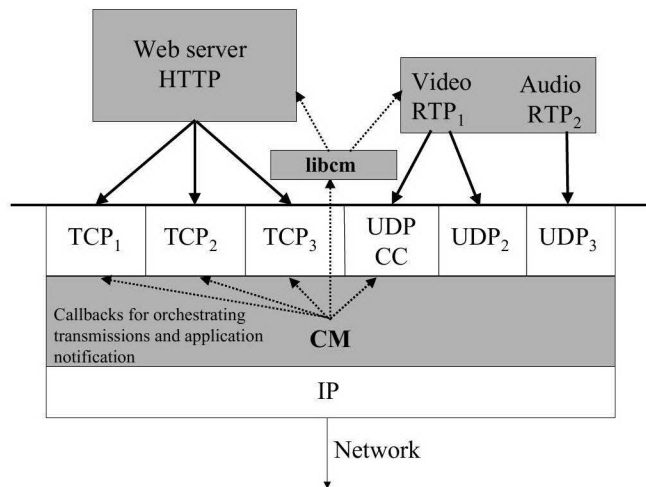

Figure 1. Architecture of the congestion manager at the data sender, showing the CM library and the CM. The dotted arrows show callbacks, and solid lines show the datapath. UDP-CC is a congestion-controlled UDP socket implemented using the CM.

scribed in Section 2.2. These components are shown in Figure 1.

When a client opens a CM-enabled socket, the CM allocates a flow to it and assigns the flow to the appropriate macroflow based on its destination. The client initiates data transmission by requesting permission to send data. At some point in the future depending on the available rate, the CM issues a callback permitting the client to send data. The client then transmits data, and tells the CM it has done so. When the client receives feedback from the receiver about its past transmissions, it notifies the CM about these and continues.

When a client makes a request to send on a flow, the scheduler checks whether the corresponding macroflow's window is open. If so, the request is granted and the client notified, upon which it may send some data. Whenever any data is transmitted, the sender's IP layer notifies the CM, allowing it to "charge" the transmission to the appropriate macroflow. When the client receives feedback from its remote counterpart, it informs the CM of the loss rate, number of bytes transmitted correctly, and the observed round trip time. On a successful transmission, the CM opens up the window according to its congestion management algorithm and attempts to grant a pending request on a flow associated with this macroflow. The scheduler also has a timer-driven component to perform background tasks and error handling.

3

2.1 CM API

The CM API is specified as a set of functions and callbacks which a client uses to interface with the CM. It specifies functions for managing state, for performing data transmissions, for applications to inform the CM of losses, for querying the CM about network state, and for constructing and splitting macroflows if the default per-destination aggregation is unsuitable for an application.

2.1.1 State management

All CM applications call cm_open() before using the CM, passing the source and destination addresses, transport-layer port numbers, and protocol numbers as arguments. This returns a CM flow identifier (cm_flowid), which is used as a handle for all future CM calls. When a flow terminates, the application is expected to call cm_close(cm_flowid) to clean up internal state. If a flow has been inactive for a pre-configured amount of time, its state in the CM is purged. Applications can also use the cm_mtu() call to obtain the maximum transmission unit (MTU, the largest unfragmented datagram size) to a destination. Inside the CM, this is either pre-configured or obtained using path MTU discovery to the receiver and cached [25].

2.1.2 Data transmission

There are three ways in which an application can use the CM to transmit data. These allow a variety of adaptation strategies, depending on the nature of the client application and its software structure.

(i) **Buffered send.** This API is similar to a conventional blocking write() call, but the resulting data transmission is paced by the Congestion Manager. We use this to implement a generic congestion-controlled UDP socket (without content adaptation), useful for bulk transmissions that do not require TCP-style reliability or fine-grained control over what data gets sent at any point in time. While this is useful for bulk data, it is not convenient for an adaptive sender that might want to revisit and change prior transmission decisions once packets are buffered in the CM, when it learns that network conditions have appreciably changed.

(ii) **Request/callback.** This is the preferred mode of communication for adaptive senders that are based on the ALF principle. Here, the client does not send any data via the CM; rather, it makes a cm_request(cm_flowid) call and expects a notification (implemented as a well-known cmapp_send() client callback) at some point in the future when this request is granted by the CM. This approach puts the sender in firm control of deciding what to transmit at any point in time and allows it to track fine-grained changes in available bandwidth. It allows the sender to adapt to sudden changes in network performance, which is hard to do in a conventional buffered transmission API. The client callback is a grant for the flow to send up to MTU bytes of data. Observe that cm_request() does not take the number of bytes or MTU-sized units as an argument; each call to cm_request() is an implicit request for sending up to MTU bytes. This simplifies the internal implementation of the CM scheduler and congestion controller at the expense of a slightly more complex interface This API is ideally suited for an implementation of TCP, since it needs to make a decision at each stage about whether to retransmit a segment or send a new one.

(iii) **Rate callback.** A self-timed application (eg. vat which samples periodically from the audio device) transmitting on a fixed schedule may receive callbacks from the CM notifying it when the parameters of its communication channel have changed, so that it can change the frequency of its timer loop or its packet size. Such clients do not use the request/callback API—if clients want their transmissions time-synchronized, they do it themselves—the CM provides the necessary information via the cmapp_update() callback that informs the client of the current rate available to it, the round-trip time, and packet loss rate along the path. The client registers a callback threshold using the cm_thresh(down, up) call; if the rate reduces by a factor of down or increases by a factor of up, the CM calls cmapp_update(). This transmission API is ideally suited for streaming layered audio and video.

2.1.3 Application notifications

One of the goals of our work was to investigate a CM implementation that made no kernel changes or installed additional software at receivers on the Internet. Since performing congestion management requires feedback about transmissions, the CM provides clients with functions to provide it with feedback. A client calls cm_update(cm_flowid, nsent, nrecd, lossmode, rtt) to inform the CM about the number of sent and received packets, type of congestion loss if any, and a round-trip time sample. The CM distinguishes between "persistent" congestion as would occur on a TCP timeout, versus "transient" congestion when only one packet in a window is lost. It also allows congestion to be notified using Explicit Congestion Notification (ECN) [32], which uses packet markings rather than drops to infer congestion.

To perform accurate bookkeeping of the congestion window and outstanding bytes for a macroflow, the CM needs to know of each successful transmission

from the host. Rather than encumber clients to report this information, we modify the IP output routine to call `cm_notify(cm_flowid, nsent)` on each transmission. (The IP layer obtains the `cm_flowid` using a well-defined CM interface that takes the flow parameters (addresses, ports, protocol field) as arguments.) However, if a client decides not to transmit any data upon a `cmapp_send()` callback invocation, it is expected to call `cm_notify(dst, 0)` to allow the CM to permit some other flows on the macroflow to transmit data.

2.1.4 Querying

If a client wishes to learn about its (per-flow) available bandwidth and round-trip time, it can use the `cm_query()` call that returns these quantities. This is especially useful at the beginning of a stream when clients can make an informed decision about the data encoding to transmit (e.g., a large color or smaller greyscale image).

2.1.5 Macroflow management

One of the decisions the CM needs to make is the granularity at which a macroflow is constructed, by deciding which flows belong to a single macroflow and share congestion information. While the default is per-destination sharing, the CM API also provides two functions that allow applications to decide which of their streams ought to belong (or not belong) to the same macroflow.

`cm_getmacroflow(cm_flowid)` returns a unique macroflow identifier, while `cm_setmacroflow(cm_macroflowid, cm_flowid)` sets the macroflow of the flow `cm_flowid` to `cm_macroflowid`. If the `cm_macroflowid` that is passed to `cm_setmacroflow()` is -1, then a new macroflow is constructed and this is returned to the caller. Each call to `cm_setmacroflow()` overrides the previous macroflow association for the flow, should one exist. We expect this API to become useful as the CM starts getting deployed over networks with service differentiation, such as differentiated services.

2.2 libcm: The CM library

The CM library provides the user with the convenience of a callback-based API while separating them from the details of how the kernel to user callbacks are implemented. While direct function callbacks are convenient and efficient in the same address space, as is the case when the kernel TCP is a client of the CM, callbacks from the kernel to user code in conventional operating systems are more difficult. A key decision in the implementation of libcm was choosing a kernel/user interface that maximizes portability, and minimizes both performance overhead and the difficulty of integration with existing applications. The resulting interface is:

1. `select()` on a single per-application CM control socket. The write bit indicates that a flow may send data, and the exception bit indicates that network conditions have changed.

2. Perform an `ioctl` to extract a list of all flow IDs which may send, or to receive the current network conditions for a flow.

2.2.1 Implementation alternatives

We considered a number of mechanisms with which to implement libcm. In this section, we discuss our reasons for choosing the control-socket+select+ioctl approach.

While much research has focused on reducing the cost of crossing the user/kernel boundary (extensible kernels in SPIN [6], fast, generic IPC in Mach [4], etc.) many conventional operating systems remain limited to more primitive methods for kernel-to-user notification, each with their own advantages and disadvantages. While functionality like the Mach port set-based IPC would be ideal for our purposes, pragmatically we considered four common mechanisms for kernel to user communication: Signals, system calls, semaphores, and sockets. A discussion of the merits of each follows.

Signals have several immediate drawbacks. First, if the CM were to appropriate an existing signal for its own use, it might conflict with an application using the same signal. Avoiding this conflict would require the standardization of a new signal type, a process both slow and of questionable value, given the existence of better alternatives. Second, the cost to an application to receive a signal is relatively high, and some legacy applications may not be signal-safe. While the new POSIX 1003.1b [16] soft realtime signals allow delivering a 32-bit quantity with a signal, applications would need to follow up a signal with a system call to obtain all of the information the kernel wished to deliver, since multiple flows may become ready at once. For these reasons, we consider mandating the use of signals the wrong course for implementing the kernel to user callbacks. However, we provide an *option* for processes to receive a `SIGIO` when their control socket status changes, akin to POSIX asynchronous I/O.

System calls that block do not integrate well with applications that already have their own event loop, since without polling, applications cannot wait on the results of multiple system calls. A system call is able to return immediately with the data the user needs, but the impediments it poses to application integration are large. System calls would work well in a threaded environment, but this presupposes threading support, and the select-based mechanism we describe below can be used in a threaded system without major additional overhead.

Semaphores suffer from the immediate drawback that they are not commonly used in network applica-

tions. For an application that uses `semop` on an array of semaphores as its event loop, a CM semaphore might be the best implementation avenue, for many of the same reasons that we chose sockets for network-adaptive applications. However, most network applications use socket sets instead of semaphore sets, and sockets have a few other benefits, which we discuss next.

Sockets provide a well-defined and flexible interface for applications in the form of the `select()` system call, though they have a downside similar to that of signals: an application wishing to receive a notification via a socket in a non-blocking manner must `select()` on the socket, and then perform a system call to obtain data from the socket. However, a select-based interface meshes well with many network applications that already have a select-loop based architecture. Utilizing a control socket also helps restrict the code changes caused by the CM to the networking stack.

Finally, we decided to use a single control socket instead of one control socket per flow to avoid unnecessary overhead in applications with large numbers of open socket descriptors, such as `select()`-based web-servers and caches. Because some aspects of select scale linearly with the number of descriptors, and many operating systems have limits on the number of open descriptors, we deemed doubling the socket load for high-performance network applications a bad idea.

2.2.2 Extracting data from the socket

Select provides notification that "some event" has occured. In theory, 7 different events could be sent by abusing the read, write, and exception bits, but applications need to extract more information than this. The CM provides two types of callbacks. Generally speaking, the first is a "permission to send" callback for a particular flow. To maintain fairness, a loose ordering should be preserved with these messages, but exact ordering is unimportant provided no flows are ignored until the application receives further updates (thereby starving the flows). If multiple permission notifications occur, the application should receive *all* of them so it can send data on all available flows. The second callback is a "status changed" notification. If multiple status changes occur before the application obtains this data from the kernel, then only the *current* status matters.

The weak ordering and lack of history prompted us to choose using an `ioctl`-based query instead of a `read` or message queue interface, minimizing the state that must be maintained in the kernel. Status updates simply return the current CM-maintained network state estimate, and "who can send" queries perform a select-like operation on the flows maintained by the kernel, requiring no extra state, instead of a potentially expensive per-process message queue or data stream. Returning all available flows has an added benefit of reducing the number of system calls which must be made if several

flows become ready simultaneously.

3 Engineering Network-adaptive Applications

In this section, we describe several different classes of applications, and describe the ways those applications can make use of the CM. We explore two in-kernel clients, and several user-space data server programs, and examine the task of integrating each with the CM.

3.1 Software Architecture Issues

Typical network applications fall into one of several categories:

- Data-driven: Applications that transmit prespecified data, such as a single file, then exit.

- Synchronous event-driven: Self-timed data delivery servers, like streaming audio servers.

- Asynchronous event-driven: File servers (http, ftp) and other network-clocked applications.

The CM library provides several options for adaptive applications that wish to make use of its services:

1. Data-driven applications may use the buffered send API to efficiently pace their data transmissions.

2. An application may operate in an entirely callback-based manner by allowing `libcm` to provide its own event loop, calling into the application when flows are ready. This is most useful for applications coded with the CM in mind.

3. Existing signal-driven applications may request a SIGIO notification from the CM when an event occurs

4. Existing applications with select-based event loops can simply add the CM control socket into their select set, and call the `libcm` dispatcher when the socket is ready. Rate-clocked applications (or pure polling-based applications) can perform a similar nonblocking select test on the descriptor when they awaken to send data, or, if they `sleep`, can replace the sleep with a timed blocking `select` call.

5. Applications may poll the CM on their own schedule.

6. Finally, applications may perform CM `ioctl()`s directly, though this creates potential portability and maintenence problems.

The remainder of this section describes how particular clients use different CM APIs, from the low-bandwidth `vat` audio application, to the performance-critical kernel TCP implementation.

3.2 TCP

We implemented TCP as an in-kernel CM client. TCP/CM offloads all congestion control to the CM, while retaining all other TCP functionality (connection establishment and termination, loss recovery and protocol state handling). TCP uses the request/callback API as low-overhead direct function calls in the same protection domain. This gives TCP the tight control it needs over packet scheduling. For example, while the arrival of a new acknowledgement typically causes TCP to transmit new data, the arrival of three duplicate ACKs instead causes TCP to retransmit an old packet.

Connection creation. When TCP creates a new connection via either `accept` (inbound) or `connect` (outbound), it calls `cm_open()` to associate the TCP connection with a CM flow. Thereafter, the pacing of outgoing data on this connection is controlled by by the CM. When application data becomes available, after performing all the non-congestion-related checks (e.g., the Nagle algorithm [40], etc.) data is queued and `cm_request()` is called for the flow. When the CM scheduler schedules the flow for transmission, the `cmapp_send()` routine for TCP is called. The `cmapp_send()` for TCP transmits any retransmission from the retransmission queue. Otherwise, it transmits the data present in the transmit socket buffer by sending up to one maximum segment size of data per call. Finally, the IP output routine calls `cm_notify()` when the data is actually sent out.

TCP input. The TCP input routines now feedback to the CM. Round trip time (RTT) sample collection is done as usual using either RFC 1323 timestamps [18] or Karn's algorithm [20] and is passed to CM via `cm_update()`. The smoothed estimates of the RTT (`srtt`) and round-trip time deviation are calculated by the CM, which can now obtain a better average by combining samples from different connections to the same receiver. This is available to each TCP connection via `cm_query()`, and is useful in loss recovery.

Data acknowledgements. On arrival of an ACK for new data, the TCP sender calls `cm_update()` to inform the CM of a successful transmission. Duplicate acknowledgements cause TCP to check its dupack count (`dup_acks`) and take appropriate action (as per TCP semantics). If `dup_acks` < 3, then TCP does nothing. If `dup_acks` == 3, then TCP assumes a packet loss, and calls `cm_update` to inform the CM of the loss. TCP also enqueues a retransmission of the lost segment and calls `cm_request()`. If `dup_acks` > 3, TCP assumes that a segment reached the receiver and caused this ACK to be sent. It therefore calls `cm_update()`. When the TCP retransmission timer expires, the sender identifies that a segment has been lost and calls `cm_update` with CM_PERSISTENT option set to signify the occurrence of persistent congestion to the CM. TCP also enqueues a retransmission of the lost segment and calls `cm_request()`.

TCP/CM Implementation. The integration of TCP and the CM required less than 100 lines of changes to the existing TCP code, demonstrating both the flexibility of the CM API and the low programmer overhead of implementing a complex protocol with the Congestion Manager.

3.3 Congestion-controlled UDP sockets

The CM also provides congestion-controlled UDP sockets. They provide the same functionality as standard Berkeley UDP sockets, but instead of immediately sending the data from the kernel packet queue to lower layers for transmission, the buffered socket implementation makes calls to the API exported by the CM inside the kernel and gets callbacks from the CM. When a CM UDP socket is created, it is bound to a particular flow. Later, when data is added to the packet queue, `cm_request()` is called on the flow associated with the socket. When the CM schedules this flow for transmission, it calls `udp_ccappsend()` in the CM UDP module. This function transmits one MTU from the packet queue, and schedules transmission for any remaining packets. The in-kernel implementation of the CM UDP API adds no additional data copies or queue structures, and all standard UDP options are supported. Modifying existing applications to use this API requires only providing feedback to the CM, and setting a socket option on the socket.

A typical client of the CM UDP sockets will behave as follows, after its usual network socket initialization:

```
flow = cm_open(dst, port)
setsockopt(flow, ..., CM_BUF)
loop:
  <send data on flow>
  <receive data acknowledgements>
  cm_update(flow, sent, received, ...)
```

3.4 Streaming Layered Audio and Video

Streaming layered audio or video applications that have a number of discrete rates at which they can transmit data are well-served by the CM rate callbacks. Instead of requiring a comparatively expensive notification for each transmission, these applications are instead notified only in the rare event that their network conditions change significantly. Layered applications open their usual UDP socket, call `cm_open()` to obtain a control socket. They operate in their own time event loop while listening for status changes on their control socket, or via a SIGIO, depending on their implementation. They use `cm_thresh()` to inform the CM about changes for which they should receive callbacks.

3.5 Real-time Adaptive Applications

Applications that desire to control which data is being sent in real-time (i.e. those that do not want any buffering inside the kernel) use the request callback API provided by the CM. On a callback from CM for transmission of data, they may use `cm_query()` to discover the network characteristics and adapt their content based on that. Other servers may simply wish to send the most up-to-date content possible, and so will defer their data collection until they know they can send it. The rough sequence of CM calls that are made to achieve this in the application are:

```
flow = cm_open(dst)
cm_request(flow)
<receive cmapp_send() callback from libcm>
cm_query(flow, ...)
<send data>
cm_notify(flow, amount of data sent)
<receive data acks>
cm_update(flow, sent, lost, ...)
```

Other options exist for applications that wish to exploit the unique nature of their network utilization to reduce the overhead of using the services of the Congestion Manager. We discuss one such option below in the manner in which we adapted the `vat` interactive audio application to use the CM.

3.6 Interactive Real-time Audio

The vat application provides a constant bit-rate source of interactive audio. Its inability to downsample its audio reduces the avenues it has available for bandwidth adaptation. Therefore, the best way to make vat behave in a network-friendly and backwards compatible manner is to preemptively drop packets to match the available network bandwidth. There are, of course, complications. Network applications experience two types of variation in available network bandwidth: long term variations due to changes in actual bandwidth, and short term variations due to the probing mechanisms of the congestion control algorithm. Short-term variation is typically dealt with by buffering. Unfortunately, buffering, especially FIFO buffering with drop-tail behavior, the de-facto standard for kernel buffers and network router buffers, can result in long delay and significant delay variation, both of which are detrimental to vat's audio quality. vat therefore needs to act like an ALF application, managing its own buffer space with drop-from-head behavior when the queue is full.

The resulting architecture is detailed in figure 2. The input audio stream is first sent to a policer, which provides long-term adaptation via preemptive packet dropping. The policer outputs into the application level buffer, which can be configured in various sizes and drop policies. This buffer feeds into the kernel buffer on-demand as packets are available for transmission.

Figure 2. The adaptive vat architecture

4 Experiments

This section describes several experiments that quantify the costs and benefits of our CM implementation. Our experiments show that using the Congestion Manager in the kernel has minimal costs, and that even the worst-case overhead of the request/callback user-space API is acceptably small.

Performance tests were performed on the Utah Network Testbed [21] using 350MHz Intel Pentium II processors, 128MB PC100 ECC SDRAM, and Intel EtherExpress Pro/100B Ethernet cards, connected via 100Mbps Ethernet through an Intel Express 510T 24 port 10/100Mbps Switch, with Dummynet channel simulation. CM tests were run with Linux 2.2.9, with Linux and FreeBSD clients.

To ensure the proper behavior of a flow, the congestion control algorithm must behave in a "TCP-compatible" [7] manner. The CM implements a TCP-style window-based AIMD algorithm with slow start. It shares bandwidth between eligible flows in a round-robin manner with equal weights on the flows.
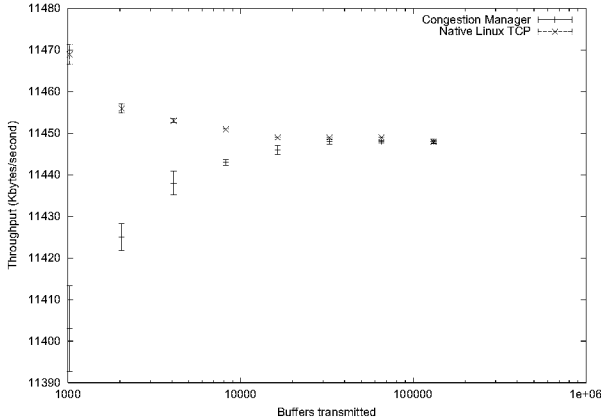

Figure 4. 100Mbps TCP throughput comparison. Note that the absolute difference in the worst case between the Congestion Manager and the native TCP is only 0.5%.

Figure 5. CPU overhead comparison between TCP/Linux and TCP/CM. For long connections, the CPU overhead converges to slightly under 1% for the unoptimized implementation of the CM.

Figure 3 shows the throughput achieved by the Linux TCP implementation (TCP/Linux) and TCP with congestion control performed by the CM (TCP/CM). There are slight algorithmic differences between the two which lead to the small differences in observed throughput, but the congestion control provided by the Congestion Manager still behaves in a network-friendly manner.

4.1 Kernel Overhead

To measure the kernel overhead, we measured the CPU and throughput differences between the optimized TCP/Linux and TCP/CM. The midrange machines used in our test environment are sufficiently powerful to saturate a 100Mbps Ethernet with TCP traffic.

There are two components to the overhead imposed by the congestion manager: The cost of performing accounting as data is exchanged on a connection, and a one-time connection setup cost for creating CM data structures. A microbenchmark of the connection establishment time of a TCP/CM vs. TCP/Linux indicates that there is no appreciable difference in connection setup times.

We used long (megabytes to gigabytes) connections with the `ttcp` utility to determine the long-term costs imposed by the congestion manager. The impact of the CM on extremely long term throughput was negligible: in a 1 gigabyte transfer, the congestion manager achieved identical performance (91.6 Mbps) as native Linux. On shorter runs, the throughput of the CM diverged slightly from that of Linux, but only by 0.5%. The throughput rates are shown in figure 4. The difference is due to the more conservative initial window opening in the CM, not CPU overhead.

Because both implementations are able to saturate

the network connection, we looked at the CPU overhead incurred during these transmissions to determine the steady-state overhead imposed by the Congestion Manager. Figure 5 compares the CPU utilization of the TCP/Linux and TCP/CM.

With long-running connections, the CPU overhead converged to slightly less than a 1% difference between the CM and the non-CM kernels. With shorter connections, the noise in the CPU overhead was too large for statistically significant conclusions, but the processor utilizations all lie within the same small ranges.

4.2 User-space API Overhead

The overhead incurred by our adaptation API is primarily in the form of extra user/kernel boundary crossings (`select()` and `ioctl()` system calls). A request/callback client is notified for each packet it may send, and so represents the worst case overhead. The buffered send API has overhead similar to that of in-kernel TCP, and the overhead imposed by the rate change notification API varies with the frequency with which rates change, but in most situations is quite low.

To measure the API overhead, we compared the CPU utilization of the `ttcp` benchmark using the kernel TCP to a user-space program sending UDP packets scheduled by the CM. `ttcp` was modified to force the kernel to use a small segment size, resulting in transmission behavior identical to the user-space program. The test scenario was two machines connected via a 5Mbps link with a 40ms round trip delay. (These test parameters were chosen to minimize the impact that the delay software would have on accuracy.) The external behavior of the two programs is very similar—both send a series of packets with TCP-style congestion avoidance. By removing competing traffic, overhead due to TCP
9

Figure 6. API Overhead. When sending small packets, the API imposes measurable overhead, but even with the relatively modest processors in our test setup, the request/callback API is able to saturate a 100Mbps link with 900 byte and larger packets.

Figure 7. Sharing TCP state: The client requests the same file 8 times with a 500ms delay between requests. By sharing congestion information, the CM-enabled server is able to provide faster service for subsequent requests.

retransmissions was minimized.

Using the request/callback API imposed between 2.5% to 18.5% additional CPU load, varying with packet size. To put this in perspective, with the modest 350 Mhz processors in our testbed, our application was still able to saturate a 100Mbps Ethernet link when sending packets of 900 bytes or larger.

Note that a real application that desired this behavior would be better served by using the buffered send API, which has much less overhead. The request/callback API is designed for applications that need last-minute control of their packet scheduling, for whom the additional overhead is a worthwhile trade-off for increased functionality.

4.3   Benefits of Sharing

One benefit of integrating congestion information with the CM is immediately clear. A client that sequentially fetches files from a webserver with a new TCP connection each time loses its prior congestion information, but with concurrent connections with the CM, the server is able to use this information to start subsequent connections with more accurate congestion windows. Figure 7 shows a test we performed across the vBNS between MIT and the University of Utah, where an unmodified (non-CM) client performed 8 retrievals of the same 128k file with a 500ms delay between retrievals, resulting in a 20% improvement in the transfer time for the later requests. (Other file sizes and delays yield similar results.) This pattern of multiple connections is still quite common in webservers despite the adoption of persistent connections: Many browsers and servers open 4 concurrent connections to a server, and many servers do not support persistent connections.
The higher initial time is due to the CM's more conservative initial window opening.

4.4   Adaptive Applications

In this section, we demonstrate some of the network adaptive behaviors enabled by the CM.

As noted earlier, applications that require tight control over data scheduling use the request/callback (ALF) API, and are notified by the CM as soon as they can transmit data. The behavior of an adaptive layering application run across the Internet between MIT and the University of Utah using this API is shown in figure 8. This application chooses a layer to transmit based upon the current rate, but sends packets as rapidly as possible to allow its client to buffer more data. We see that the CM is able to provide sufficient information to the application to allow it to adapt properly to the network conditions.

For self-clocked applications that base their transmitted data upon the bandwidth to the client (such as conventional layered audio servers), the CM rate callback mechanism provides a low-overhead mechanism for adaptation, and allows clients to specify threshholds for the notification callbacks. Figure 9 shows application adaptation using rate callbacks for a connection between MIT and University of Utah. Here, the application decides which of the four layers it should send based on notifications from the CM about rate changes.

From figures 8 and 9, we see from the increased oscillation rate in the transmitted layer that the ALF application is more responsive to smaller changes in available bandwidth, whereas the rate callback application relies occasionally on short-term kernel buffering for smoothing. There is an overhead vs. functionality trade-off
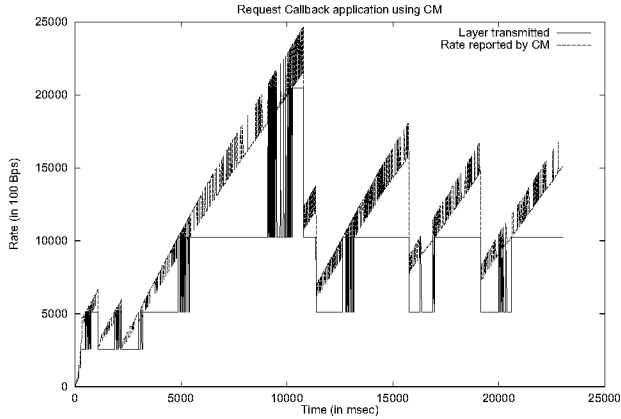

10

**Figure 8**. Adaptive layered application using request callback (ALF) API

Figure 9. Adaptive layered application using rate callback API

**Figure 10**. Adaptive layered application using rate callback API with delayed feedback

involved in the decision of which API to use, given the higher overhead of the ALF API, but applications face a more important decision about the behavior they wish to exhibit.

Some applications may be concerned about the overhead from receiver feedback. To mitigate this, an application may delay sending feedback; we see this in a minor and inflexible way with TCP delayed acks. In figure 10, we see that delaying feedback to the CM causes burstiness in the reported bandwidth. Here, the feedback by the receiver was delayed by min(500 acks, 2000ms). The initial slow start is delayed by 2s waiting for the application, then the update causes a large rate change. Once the pipe is sufficiently full, 500 acks come relatively rapidly, and the normal, though bursty, non-timeout behavior resumes.

5 Discussion

We have shown several benefits of integrated flow management and the adaptation API, and have explored the design features that make the API easy to use. This section describes an optimization useful for busy servers, and discusses some drawbacks of the current CM architecture.

Optimizations. Servers with large numbers of concurrent clients are often very sensitive to the overhead caused by multiple kernel boundary crossings. To reduce this overhead, we can batch several sockets into the same cm_request call with the cm_bulk_request call, and its corresponding bulk query, notify, and update calls.

By multiplexing control information for many sockets on each CM call, the overhead associated with multiple kernel crossing is avoided, at the expense of managing more complicated data structures for the CM interface. The bulk querying is already performed in libcm when multiple flows are ready during a single ioctl to determine which flows can send data, but this completes the interface.

Trust issues. Because our goal was an architecture that did not require modifications to receivers, we devised a system where applications provide feedback using the cm_update() call. The consequence of this is that there is a potential for misuse, due to bugs or malice. For example, the CM client could repeatedly misinform the CM about the absence of congestion along a path and obtain higher bandwidth. We do not believe that this in any way increases the vulnerability of the Internet to such problems because this is easy to do today. More important is the possibility of an application to falsely report congestion along a path and prevent another flow on the same macroflow, but belonging to a different process, from making progress. While this is a possibility, we believe that the incentive for such be-

11

havior is small, since the malicious flow would also get low performance. Furthermore, we intend to explore macroflow-splitting algorithms that dynamically adjust the composition of macroflows based on flows sharing common performance. Another form of abuse is when a malicious receiver attempts to defeat congestion control, as pointed out [37]. The techniques proposed there can be used in the CM as well.

Macroflow construction Some Internet Service Providers deploy network-layer load balancers that route packets belonging to different flows along different paths inside the network, which might violate the granularity assumptions made in the CM. However, unless such balancers are careful, they would route packets on the same TCP connection along different paths, which would confound its loss recovery and reordering-detection schemes. We observe that as long as such load balancers work on the granularity of host addresses, there will be no problems for the CM to tackle.

When differentiated services start being deployed, the CM would have to reconsider the default choice of a macroflow. We expect to be able to gain some benefit by including the IP differentiated-services field in deciding the composition of a macroflow.

Finally, we observe that remote LANs are not often the bottleneck for an outside communicator. As suggested in [42, 36] among others, aggregating congestion information about remote sites with a shared bottleneck and sharing this information with local peers may benefit both users and the network itself. A macroflow may thus be extended to cover multiple destination hosts, all behind the same shared bottleneck link. The efficient determination of such bottlenecks remains an open research problem.

6 Related work

Designing adaptive network applications has been an active area of research for the past several years. In 1990, Clark and Tennenhouse [10] advocated the use of *application-level framing* (ALF) for designing network protocols, where protocol data units are chosen in concert with the application. Using this approach, an application can have a greater influence over deciding how loss recovery occurs than in the traditional layered approach. The ALF philosophy has been used with great benefit in the design of several multicast transport protocols including the Real-time Transport Protocol (RTP) [38], frameworks for reliable multicast [13, 33], and Internet video [23, 35].

Adaptation APIs in the context of mobile information access were explored in the Odyssey system [26]. Implemented as a user-level module in the NetBSD operating system, Odyssey provides API calls by which applications can manage system resources, with upcalls to applications informing them when changes occur in the resources that are available. In contrast, our CM system is implemented in-kernel since it has to manage

and share resources across applications (e.g., TCP) that are already in-kernel. This necessitates a different approach to handling application callbacks. In addition, the CM approach to measuring bandwidth and other network conditions is tied to the congestion avoidance and control algorithms, as compared to the instrumentation of the user-level RPC mechanism in Odyssey. We believe that our approache to providing adaptation information for bandwidth, round-trip time, and loss rate complements Odyssey's management of disk space, CPU, and battery power.

The CM system uses application callbacks or *up-calls* as an abstraction, an old idea in operating systems. Clark describes upcalls in the Swift operating system, where the motivation is a lower layer of a protocol stack synchronously invoking a higher-layer function across a protection boundary [8]. The Mach system used the notion of *ports*, a generic communication abstraction for fast inter-process communication (IPC). POSIX specifies a standard way of passing "soft real-time signals" that can be used to send a notification to a user-level process, but it restricts the amount of data that can be communicated to a 32-bit quantity.

Event delivery abstractions for mobile computing have been explored in [1], where "monitored" events are tracked using polling and "triggered" events (e.g., PC card insertion) are notified using IPC. This work defines a language-level mechanism based on C++ objects for event registration, delivery, and handling. This system is implemented in Mach, using its ports as the abstraction.

Our approach is to use a `select()` call on a control socket to communicate information between kernel and user-level. The recent work of Banga *et al.* to improve the performance of this type of event delivery can be used to further improve our performance.

The Microsoft Winsock implementation is largely callback-based, but here callbacks are implemented as conventional function calls since Winsock is a user-level library within the same protection boundary as the application [31]. The main reason we did not implement the CM as a user-level daemon was because TCP is already implemented in-kernel in most UNIX operating systems, and it is important to share network information across TCP flows.

Quality-of-service (QoS) interfaces have been explored in several operating systems, including Nemesis [15]. Like the exokernel approach [19] and SPIN [6], Nemesis enables applications to perform as much of the processing as possible on their own using application-specific policy, supported by a different set of operating system abstractions from UNIX. Whereas Nemesis treats local network-interface bandwidth as the resource to be managed, we take a more end-to-end approach of discovering the end-to-end performance to different end-hosts, enabling sharing across common network paths. Furthermore, the API exported by Nemesis is useful for applications that can make resource reser-

vations, while the CM API provides information about network conditions.

Multiple concurrent streams can cause problems for TCP congestion control. First, the ensemble of flows probes more aggressively for bandwidth than a single flow. Second, upon experiencing congestion along the path, only a subset of the connections usually reduce their window. Third, these flows do not share any information between each other. While we propose a general solution to these problems, application-specific solutions have been proposed in the literature. Of particular importance are approaches that multiplex several logically distinct streams onto a single TCP connection at the application level, including Persistent-connection HTTP (P-HTTP [28], part of HTTP/1.1 [11]), the Session Control Protocol (SCP) [39], and the MUX protocol [14]. Unfortunately, these solutions suffer from two important drawbacks. First, because they are application-specific, they require each class of applications (Web, real-time streams, file transfers, etc.) to reimplement much of the same machinery. Second, they cause an undesirable coupling between logically different streams: if packets belonging to one of the streams is lost, another stream could stall even if none of its packets are lost because of the in-order "linear" delivery forced by TCP. Independent data units belonging to different streams are no longer independently processible and the parallelism of downloads are often lost.

7 Conclusion

The CM system enables applications to obtain an unprecedented degree of control over what they can do in response to different network conditions. It incorporates robust congestion control algorithms, freeing each application from having to reimplement them. It exposes a rich API that allows applications to adapt their transmissions at a fine-grained level, and allows the kernel and applications to integrate congestion information across flows.

The implementation of the CM provides easy-to-use facilities for congestion control and integrated flow management. Our performance evaluation shows that it is possible for an operating system to incorporate these services with low overhead.
